### Just Accepted

"Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides "Just Accepted" as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. "Just Accepted" manuscripts appear in full in PDF format accompanied by an HTML abstract. "Just Accepted" manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). "Just Accepted" is an optional service offered to authors. Therefore, the "Just Accepted" Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the "Just Accepted" Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these "Just Accepted" manuscripts.

**ABSTRACT:** The small-pore Cu-CHA zeolite is today the object of intensive research efforts aiming to rationalize its outstanding performance in the NH<sub>3</sub>-assisted selective catalytic reduction (SCR) of harmful nitrogen oxides and to unveil the SCR mechanism. Herein we exploit *operando* X-ray spectroscopies to monitor the Cu-CHA catalyst *in action* during NH<sub>3</sub>-SCR in the 150–400 °C range, targeting Cu oxidation state, mobility and preferential N or O ligation as a function of reaction temperature. By combining *operando* XANES, EXAFS and vtc-XES, we unambiguously identify two distinct regimes for the atomic-scale behavior of Cu active-sites. Low-temperature SCR, up to ca. 200 °C, is characterized by balanced populations of Cu(I)/Cu(II) sites and dominated by mobile NH<sub>3</sub>-solvated Cu-species. From 250 °C upwards, in correspondence to the steep increase in catalytic activity, the largely dominant Cu-species are framework-coordinated Cu(II) sites, most likely representing the active sites for high-temperature SCR.

Recent years have seen a Renaissance for metal-exchanged zeolites. These systems are attracting growing interest as versatile platforms for novel chemistry at the boundary between homogeneous and heterogeneous catalysis. Copper, with its rich redox chemistry and exquisite coordinative flexibility, as we see in many Cu-enzymes,<sup>1,2</sup> is the ideal candidate for single-site catalysis empowered by host-guest interactions inside the zeolite cages. In particular, the small-pore Cu-CHA zeolite is today the object of intensive research efforts aiming to rationalize its outstanding performance in the NH<sub>3</sub>-assisted selective catalytic reduction (SCR) of harmful nitrogen oxides.<sup>3–7</sup> Cu-CHA is currently commercialized due to its enhanced activity, selectivity and hydrothermal stability<sup>8</sup> with respect to other zeolite-based catalysts. Nonetheless, despite the recent advances in the understanding of the SCR mechanism on Cu-CHA,<sup>6,9–15</sup> several questions still need to be addressed to design deNO<sub>x</sub> catalysts able to keep pace with the increasingly stricter regulations worldwide.

The powerful experimental and theoretical methods matured in the last decade are enabling an unprecedented molecular-level understanding of the structure-composition-activity relationship in Cu-zeolites. Very recently, Schneider and co-workers<sup>15</sup> have synergized experiment and theory to correlate the compositional parameters in Cu-CHA and the types/numbers of Cu-sites formed

after dehydration and in SCR-relevant conditions. The authors demonstrated that during dehydration Cu(II) ions first populate *2Al* sites in the 6-membered rings (*6r*) of the CHA framework (Z<sub>2</sub>-Cu(II), where Z<sub>2</sub> denotes 2 neighboring charge-balancing framework Al sites), identified as the most energetically favoured exchange sites for “naked” Cu(II) ions.<sup>16,17</sup> Once the less reducible<sup>11,15,18,19</sup> Z<sub>2</sub>-Cu(II) sites are saturated, Cu cations are stabilized in proximity of isolated *1Al* sites as redox-active Z-[Cu(II)OH]<sup>+</sup> complexes (where Z denotes an isolated framework Al site), representing the largely dominant coordination environment at high Cu-loading.<sup>19,20</sup> Importantly, the chemical and spectroscopic distinction between these two types of Cu-sites is much less pronounced when the catalyst is exposed to the SCR feed or partial mixtures of SCR reactants. Consistently with previous reports,<sup>21,22</sup> *operando* XANES during SCR at 200 °C revealed the presence of a ca. 50/50% Cu(I)/Cu(II) mixture. Paolucci *et al.*<sup>15</sup> associated the Cu(I) and Cu(II) components to the most stable species evidenced by DFT: Z[Cu(I)(NH<sub>3</sub>)<sub>2</sub>] (also observed after exposure to the NO+NH<sub>3</sub> mixture at 200 °C, as was reported before<sup>12,13,23</sup>) and Z[Cu(II)OH(NH<sub>3</sub>)<sub>3</sub>] on *1Al* sites; Z<sub>2</sub>[Cu(II)(NH<sub>3</sub>)<sub>4</sub>] and ZNH<sub>4</sub><sup>+</sup>/Z[Cu(I)(NH<sub>3</sub>)<sub>2</sub>] on *2Al* sites. On this basis, NH<sub>3</sub>-solvated Cu-complexes, scarcely interacting with CHA framework and poorly influenced by Al distribution, are proposed as the SCR active sites at 200 °C. On the other hand, the authors suggest that NH<sub>3</sub> de-solvation at higher temperature is expected to influence the SCR rates, especially in the oxidation half-cycle. Since no evidences on this key aspect have been reported so far, a temperature-dependent investigation of the Cu-CHA catalyst *in action* during NH<sub>3</sub>-SCR becomes crucial to pinpoint alternative reaction pathways and Cu active species as a function of the operation temperature. To bridge this gap, we monitored Cu-CHA during NH<sub>3</sub>-SCR in the 150–400 °C range by *operando* XAS and XES. As illustrated in a number of recent reviews,<sup>5,7,24</sup> these X-ray spectroscopies<sup>25–31</sup> are ideal to track the properties of Cu cations in zeolites, and allowed us to determine (i) oxidation state, (ii) mobility and (iii) preferential N or O ligation for Cu-active sites as a function of reaction temperature. From these experiments it clearly emerges that temperature strongly influences Cu-speciation during SCR, with profound implications on the elucidation of SCR active sites and mechanism. We performed *operando* XAS/XES during standard SCR (500 ppm NO, 500 ppm NH<sub>3</sub>, 5% H<sub>2</sub>O, 10% O<sub>2</sub>/He, flow rate = 300 ml/min) using a well-established gas flow setup on a Cu-CHA catalyst with composition (Si/Al=15, Cu/Al=0.48) equivalent to the one investigated in

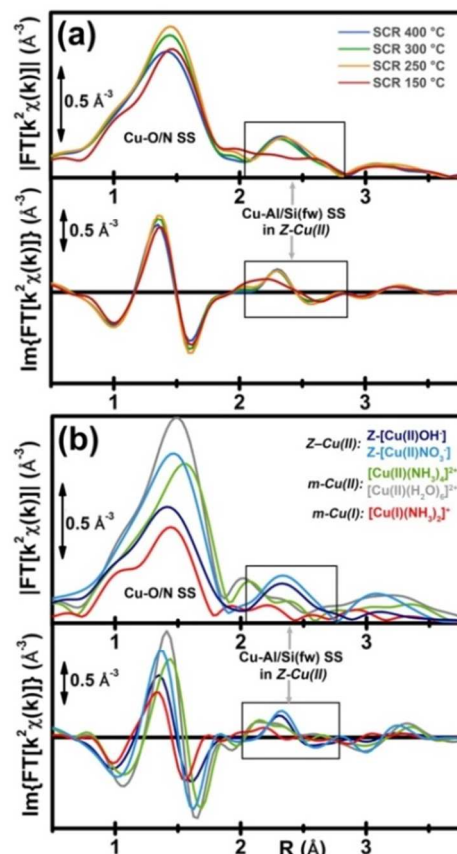

our previous studies<sup>13,19,23</sup> and selected by Paolucci *et al.*<sup>15</sup> as the reference for *1A1* site-containing Cu-CHA. In such compositional ranges, *2A1* sites are known to occur only as minority Cu-species,<sup>15,18,19</sup> and are hence not considered in the data analysis (see SI, Section 3). Additional details on sample synthesis and experimental setup are reported in SI, Section 1). A mass spectrometer downstream the reactor cell allowed us to verify that the catalyst was effectively active for SCR reaction during XAS/XES measurements, with temperature-dependent NO conversion in qualitative agreement with SCR rates obtained in dedicated laboratory tests on the same catalyst batch (see also SI, Section 2).

**Figure 1.** (a) *Operando* XANES collected during SCR at temperatures of 150, 250, 300, 400 °C. (b) XANES spectra of selected reference Cu-species employed to interpret *operando* data reported in part (a). The same vertical and horizontal axes scale is used in part (a) and (b) to facilitate a direct comparison between *operando* and reference data. The insets report a magnification of the background-subtracted Cu(II) 1s → 3d pre-edge peaks highlighted by the black boxes in the main panels.

Figure 1 shows the temperature-dependent modifications in the XANES of Cu-CHA during SCR. To guide data interpretation, *operando* XANES (Figure 1a) are compared to the ones obtained for a series of references (Figure 1b), selected considering the principal spectral features emerging during SCR. Reference XANES spectra were separately measured for Cu(I) and Cu(II) aqua/amino complexes in solution (*m*-Cu(I) and *m*-Cu(II)), *m* = “mobile”) and framework-interacting Cu(II) species in Cu-CHA (*Z*-Cu(II)), namely three-coordinated *Z*-[Cu(II)OH] and four-coordinated *Z*-[Cu(II)(NO<sub>3</sub>)<sub>2</sub>] (see SI, Section 3.1). To estimate temperature-dependent Cu-speciation during SCR, we applied linear combination fit (LCF) analysis using the reference spectra in Figure 1b (see SI, Section 3.2). The *operando* SCR XANES spectrum at 150 °C is in excellent agreement with the observations reported by Paolucci *et al.* and others<sup>15,21,22</sup> during standard SCR at 200 °C. Hence, our experimental conditions guarantee a reliable comparison with previous studies. The pre-edge peak at ca. 8977.3 eV, mostly arising from Cu(II) 1s → 3d transition,<sup>32,33</sup> is significantly lower than in Cu(II) references. The characteristic edge-rising peak at ca. 8982.5 eV deriving from 1s → 4p transition in the linear Cu(I)(NH<sub>3</sub>)<sub>2</sub> complex<sup>32,34,35</sup> is well evident. LCF

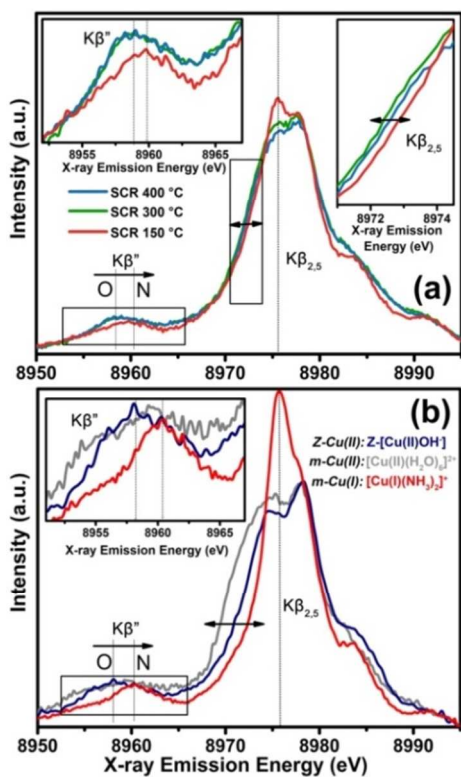

indicates a ca. 46% contribution from *m*-Cu(I), in the form of [Cu(I)(NH<sub>3</sub>)<sub>2</sub>]<sup>+</sup>, whereas the remaining XANES signal is fitted with an almost equal fraction of *Z*-Cu(II) (ca. 26%) and *m*-Cu(II) (ca. 25%) species. In other words, ‘mobile’ Cu(II) and Cu(I) sites solvated by ammonia are the main sites, in agreement with Paolucci *et al.*,<sup>15</sup> with a small fraction of Cu(II) sites interacting with the framework. Crucially, an abrupt modification in the *operando* XANES is observed from 250 °C and upwards. The contribution of *m*-Cu(I) reduces to ca. 15% and the spectral shape evolves towards the one characteristic of *Z*-Cu(II): an edge-rising shoulder at ca. 8986.6 eV and a broad white line peak centered at 8997.7 eV, typically increasing in intensity for four-coordinated *Z*-Cu(II) sites with respect to three-coordinated ones (e.g. comparing the *Z*-[Cu(II)OH] and *Z*-[Cu(II)NO<sub>3</sub>]<sup>2-</sup> references in Figure 1b).<sup>13,19</sup> *Z*-Cu(II) species collectively account for ca. 74% of Cu sites (the remaining 11% attributed to minor contributions from *m*-Cu(II) complexes). The remarkable intensity increase of the Cu(II) 1s → 3d pre-edge peak clearly indicates a largely dominant 2+ oxidation state, in agreement with LCF results. A further increase in the operation temperature induces more subtle but still appreciable modifications. At 350 °C, the relative contributions from mobile and framework-interacting species remain substantially unchanged, whereas the slight intensity decrease observed in the white line region is compatible with the partial conversion of four-coordinated *Z*-Cu(II) sites into three-coordinated ones. This trend is maintained at 400 °C. Here LCF evidences negligible contributions from *m*-Cu(I) and *m*-Cu(II) species, and largely dominant *Z*-Cu(II) sites preferentially occurring as three-coordinated sites.

**Figure 2.** (a) *Operando* phase-uncorrected FT-EXAFS spectra (moduli and imaginary parts of FT in top and bottom panel, respectively) collected during SCR at temperatures of 150, 250, 300, 400 °C. (b) Phase-uncorrected FT-EXAFS spectra of selected Cu-references employed to interpret *operando* data reported in part (a). In both part (a) and (b) all the FT-EXAFS spectra are calculated transforming *k*<sup>2</sup>-weighted  $\chi(k)$  spectra in the range 2.5-

12.4 Å<sup>-1</sup> (see SI, Section 4) and plotted using the same vertical and horizontal axes scale to facilitate a direct comparison between *operando* and reference data.

*Operando* EXAFS and XES allowed us to independently validate the XANES results described above, targeting the mobility level and the preferential O or N ligation of the Cu active sites, respectively. It is now established<sup>13,15,19,21</sup> that the well-defined maximum peaking at ca. 2.3 Å in the phase-uncorrected modulus of FT-EXAFS spectrum of dehydrated Cu-CHA derives from single-scattering paths involving Al/Si atoms of the CHA framework. Although the variable-temperature data collection and the presence of multiple Cu-species prevent a quantitative fitting of *operando* EXAFS, the second-shell peak at 2.3 Å can be exploited as a fingerprint for framework-coordinated Cu-sites. As shown in Figure 2a, this EXAFS feature is always present during SCR in the (250–400) °C range, with stable intensity and shape comparable with what observed for Z-Cu(II) references reported in Figure 2b. In the same temperature interval, we notice slight fluctuations in the first-shell intensity of the *operando* EXAFS spectra, suggesting an increase in the average first-shell coordination number as temperature decreases. Interestingly, in the high-R range, the FT-EXAFS at 250 °C seems more similar to what seen in the Z-[Cu(II)NO<sub>3</sub>]<sup>-</sup> reference, where the presence of a well-defined maximum at ca. 3.2 Å was connected multiple-scattering scattering feature peculiar of bidentate Z-[Cu(II)(NO<sub>3</sub>)<sub>2</sub>]<sup>-</sup> moieties<sup>13</sup> (see SI, Section 4). The EXAFS signature of the Cu-CHA catalyst drastically changes when SCR is run at 150 °C. The second-shell maximum is strongly perturbed and partially evolves towards the unstructured shape characteristic of *m*-Cu(I)/(II) species. The first shell intensity decreases despite the drop of thermal contribution to the Debye-Waller factors, consistently with an increase of the fraction of two-coordinated species with N/O ligands, which are hardly distinguishable by XAS.

**Figure 3.** (a) Background-subtracted *operando* XES spectra collected during SCR at temperatures of 150, 300, 400 °C. (b) Background-subtracted XES spectra of selected Cu references states formed inside the pores of Cu-CHA, representative of Z-Cu(II), *m*-Cu(II) and *m*-Cu(I) species. The insets report magnifications of

the Kβ'' satellites and, for part (a) only, of the left side of the Kβ<sub>2,5</sub> line, highlighted by the black boxes in the main panels.

As already shown in *in situ/operando* studies on Cu-CHA,<sup>14,23,36</sup> such an ambiguity regarding the type of ligands can be resolved by valence-to-core (vtc) XES, monitoring the energy position of the weak Kβ'' satellite.<sup>28,37</sup> Moreover, the overall Kβ<sub>2,5</sub> line shape is highly sensitive to local coordination geometry and symmetry and represents a valid support to qualitatively cross-check Cu-speciation from XANES.

Figure 3 shows *operando* SCR XES spectra for key temperature points (Figure 3a), together with representative reference XES data for Z-Cu(II), *m*-Cu(II) and *m*-Cu(I) species formed inside the pores of Cu-CHA (Figure 3b), see also SI Sections 1.5 and 3.1. As for *operando* XANES and EXAFS datasets, two distinct regimes can be individuated. In the high-temperature range, at 400 and 300 °C, the Kβ<sub>2,5</sub> line shape characteristic of Z-Cu(II) species is observed, and the energy position of the Kβ'' peak reveals largely dominant O-ligation. Conversely, at 150 °C the Kβ<sub>2,5</sub> line shape clearly evolves towards the one observed for Cu(I)(NH<sub>3</sub>)<sub>2</sub>, characterized by a narrow and intense peak at ca. 8976 eV. In parallel, the Kβ'' satellite significantly shifts to higher energy, unambiguously indicating a substantial increase in the fraction of N-coordinated Cu-species in the catalyst. The Kβ'' energy position observed in these conditions is intermediate between the ones observed for pure O- and pure N-ligation, in agreement with XANEX LCF analysis (60% of NH<sub>3</sub>-solvated Cu-species, largely present as [Cu(I)(NH<sub>3</sub>)<sub>2</sub>]<sup>2+</sup>, 46%). In addition, the broad feature on the low-energy side of the Kβ<sub>2,5</sub> peak, typical of hydrated Cu(II) ions (see Figure 3b, gray curve), is never observed in the *operando* XES series, supporting a very minor H<sub>2</sub>O coordination in the whole probed temperature range. Consistently with LCF XANES and with many FTIR evidences reported before,<sup>23,38</sup> in the low-temperature SCR range Cu-ions are almost exclusively solvated and mobilized by NH<sub>3</sub>.

In conclusion, *operando* XAS/XES during SCR unambiguously point out that two distinct regimes exist for the atomic-scale behavior of Cu-sites in the investigated Cu-CHA catalyst, emerging at different temperature ranges. As depicted in Figure 4, low-temperature SCR, up to ca. 200 °C, is characterized by balanced populations of Cu(I)/Cu(II) sites and dominated by mobile NH<sub>3</sub>-solvated Cu-species.

**Figure 4.** Comparison between temperature dependent NH<sub>3</sub>-SCR conversion rate and Cu-speciation in Cu-CHA. Structural snapshots of the dominant (highest relative abundance over the total number of Cu sites) model Cu-species evidenced by LCF analysis of *operando* XANES for each probed temperature are also reported, including Z-[Cu(II)OH]<sup>-</sup> and Z-[Cu(II)NO<sub>3</sub>]<sup>-</sup> in the high-temperature range and mobile Cu(I)(NH<sub>3</sub>)<sub>2</sub> complexes in the low-temperature range (atoms color code: Cu: green, O: red, Al: yellow, Si: gray, N: blue, H: white).

Noteworthy, *operando* FT-EXAFS do not show any signal ascribable to Cu-Cu scattering paths. Hence, at our experimental

conditions, most of Cu occurs as monomeric species, although a minor high-R contribution from neighboring Cu-sites, proposed to favor NO activation by O<sub>2</sub><sup>13b</sup> cannot be excluded. We fully agree with Paolucci *et al.*<sup>15</sup> in assigning the Cu(I) component to Z[Cu(I)(NH<sub>3</sub>)<sub>2</sub>] species. As for the Cu(II) component, assigned by Paolucci *et al.* to Z[Cu(II)OH(NH<sub>3</sub>)<sub>3</sub>] species, results of our LCF analysis demonstrate that it can be as well ascribed to a complex mixture of residual O-bonded Z-Cu(II) sites and *m*-Cu(II) complexes (mostly with NH<sub>3</sub> ligands). In the 250–400 °C range, a completely different scenario is revealed: Cu is largely present as framework-coordinated Z-Cu(II) species, accounting for ca. 70% to more than 90% of total Cu sites. Here, temperature-dependent dynamics seems to mostly involve Cu interaction with O-bonding extra-framework groups and reactants from the gas-phase (*e.g.* hydroxyls and bidentate nitrates/nitrites), while coordination to framework is substantially unperturbed. Very interestingly, the transition between these two regimes corresponds to the steep rise in the temperature-dependent SCR conversion rate, determined in a dedicated catalytic test (see SI, Section 1.2) and reported in Figure 4 for comparison. These novel findings evidence a profound influence of the operation conditions on Cu-speciation during NH<sub>3</sub>-SCR, which should be considered to fully unleash the potential of Cu-zeolite based deNO<sub>x</sub> catalysts.
